Abstract

In this paper I argue for a reassessment of special relativity. The fundamental theory of relativity applicable in this Universe has to be consistent with the existence of the massive Universe, and with the effects of its gravitational interaction on local physics. A reanalysis of the situation suggests that all relativistic effects that are presently attributed to kinematics of relative motion in flat space-time are in fact gravitational effects of the nearly homogeneous and isotropic Universe. The correct theory of relativity is the one with a preferred cosmic rest frame. Yet, the theory preserves Lorentz invariance. I outline the new theory of Cosmic Relativity, and its implications to local physics, especially to physics of clocks and to quantum physics. This theory is generally applicable to inertial and noninertial motion. Most significantly, experimental evidence support and favour Cosmic Relativity. There are observed effects that can be consistently explained only within Cosmic Relativity. The most amazing of these is the dependence of the time dilation of clocks on their ‘absolute’ velocity relative to the cosmic rest frame. Important effects on quantum systems include the physical cause of the Thomas precession responsible for part

*E-mail address: unni@tifr.res.in

of the spectral fine structure, and the phase changes responsible for the spin-statistics connection. At a deeper level it is concluded that relativity in flat space-time with matter reiterates Mach's principle. There will not be any relativistic effect in an empty Universe.

1 Introduction

In this introductory section I point out the need for a reassessment of Special Relativity (SR). Apart from strong theoretical motivations, in the unavoidable and inseparable presence of a vast and massive Universe, there is compelling experimental evidence that suggests that SR has to be replaced by a more fundamental theory of relativity in flat space-time. A calculation of the gravitational time dilation effects of galaxies and other masses on clocks moving relative to the CMBR rest frame shows that these effects are as large as the effects predicted by SR. But there is no room for both the kinematical SR effects and gravitational effects to be present together since experimental data at 0.1% accuracy allow only one of them to be applicable. But galaxies and the massive Universe *exist* and therefore those gravitational effects should be real and ever present. This rules out kinematics as the basis of relativistic effects, and immediately shows the need to replace special relativity with a new theory of relativity that relies on the gravitational effects of the Universe. Also, there is unambiguous evidence from experiments that there are measurable physical effects on clocks that depend on the velocity of the frame in which they are compared, with respect to a cosmic absolute rest frame determined by the average gravity of the Universe.

Our Universe, “once given” is observed to be homogeneous and isotropic on large scales. Recently it is also known that the average density of matter and energy in this Universe is very close to being ‘critical’, making the Universe spatially flat. Since we also know that the rate of expansion of the Universe is very slow at present, only about 2×10^{-18} m/s over a length scale of 1 meter, we can also take the expansion rate as negligible for time scales and length scales relevant to laboratory experiments. These facts are represented by the near equality of the Robertson-Walker metric for the Universe with matter and energy at critical density (the critical Universe), and the Minkowski metric for empty space-time. In this special situation space-time is seemingly flat even in a massive Universe in which every physical system is interacting gravitationally with a large amount of matter. But this

superficial equivalence that makes SR seemingly correct breaks in a deeper analysis.

The Special theory of Relativity was formulated in the gravity-free empty space-time and there is a general belief that the theory is correct and well tested, despite the knowledge that space-time is not empty or free of gravity. SR rejected absolute space and absolute time, it rejected preferred frames, and it rejected anything that can act as a preferred frame, like the electromagnetic ether. In SR all frames are equivalent, and no experiment within a uniformly moving frame can reveal the velocity of the frame relative to any other hypothetical absolute frame. More over, all observers in inertial motion are equivalent and any such observer is entitled to the claim of being at a ‘state of rest’, with his local clocks always registering the maximum ‘aging’ compared to any other clock *moving relative* to him.

But we know for a fact that there is a preferred frame, and also absolute time. The frame in which the Cosmic Microwave Background Radiation (CMBR) has no dipole anisotropy is the absolute rest frame, and the value of the monotonically changing temperature provides the absolute time [1]. No observer has a right to claim that he is at rest even in inertial motion, because that will be in conflict with his measurement of the properties of the Universe. How can these facts be consistent with Special Relativity?

Aren’t we misled in a serious way? Isn’t possible that the near identity of the space-time of the massive and vast Universe and that of the empty space lead us to the illusion that the correct theory of relativity is special relativity in which time and space intervals are modified by mere kinematics in empty space, with all the experimental tests seemingly matching with the predictions of SR, whereas all the effects are in fact due to the ever present gravitational interaction of the entire Universe? One may dismiss this possibility, in fact too easily, and might argue that even if that was the case, if there is no way of distinguishing between two cases – one in which all the physical effects are due to kinematics as described SR, and another in which the effects are dynamical due to the gravity of the Universe – then one may chose either as valid. Even admitting this much is a large change in our understanding of relativity, since the possibility of an equally valid new theory emerges. But, in fact, the choice does not exist because the massive Universe exists in which everything is gravitationally linked to everything else. Comparison with experimental evidence and also requirement of general applicability and consistency favour the new theory as the more correct theory of relativity in flat space-time, as we shall see.

It turns out that there are large differences between the two cases. In SR all inertial frames are equivalent. In SR the physical effects are the same irrespective of whether there is any matter in the Universe or not. In the new theory that acknowledges the presence and gravitational effect of the cosmos, which I call *Cosmic Relativity*, there is exactly one preferred frame, and all other frames are in relative motion with respect to the preferred frame. The preferred unique frame is the one that is at rest with respect to the average matter distribution, and operationally this frame is easily identified as the one in which there is no dipole anisotropy of the CMBR. The monotonically varying average temperature of the CMBR provides the absolute time for every observer. Yet, there are modifications of time and space intervals in moving frames due to the gravity of the matter in the Universe because motion modifies the gravitational potentials. In particular, *when two clocks are compared in a frame moving with respect to the cosmic frame, they will show an asymmetry in their time dilation depending on the velocity of the frame with respect to the cosmos.* A dramatic consequence is that a clock that is moving in a particular frame can ‘age’ faster than a clock that is stationary in the same frame, in complete contrast to the SR prediction where it ages slower. This remarkable prediction of Cosmic Relativity (CR) has in fact been seen in earlier clock comparison experiments. Cosmic Relativity is favoured by experimental evidence as the correct theory of relativity. The importance of a reassessment in the light of these findings and experimental evidence cannot be overemphasized, especially just before the 100th successful year of SR.

In the rest of the paper I outline the details of the new theory of Cosmic Relativity, its predictions, the differences with SR, evidence from experiments in favour of CR, other physical effects of the gravity of the Universe, especially on quantum systems, and proposal for experimental tests with observable differences from predictions of SR. Part of the paper contains results that can be considered as the quantum generalization of the Mach’s principle, but calculated directly from cosmology and a new theory of relativity.

2 Gravity of the Universe and its effect on moving clocks

2.1 Physical and mathematical framework

I now present the physical and mathematical reasoning behind the calculation of the gravitational effects on clocks moving in the cosmos. This is discussed before the full theory is discussed to contrast the new theory with SR on the basis of already available experimental results on rates of moving clocks.

In a homogenous and isotropic Universe with an ‘age’ of about 14 billion years, the gravitational potential (energy) at any point is finite when calculated as the integral effect of the potential from all the masses upto the Hubble radius. There is no spatial gradient of this potential and there are no forces. Our fundamental hypothesis of the theory, argued later, is that this average gravitational potential determines a maximum velocity for any entity moving in this cosmos, and that this constant velocity is numerically related to the potential as $c^2 = |\phi_U|$. In a relativistic theory with four-potentials or more complex structure, moving through such a cosmos will generate both a different gravitational potential, $\phi(1 - V^2/c^2)^{-1/2}$, and also a vector potential, $-\phi \frac{V}{c}(1 - V^2/c^2)^{-1/2}$. Here V is the velocity relative to the average rest frame defined by all the masses in the Universe. Clearly, there is one preferred frame in which the magnitude of the ϕ potential is minimum. In all other frames moving relative to such a cosmic rest frame, the gravitational potential has higher magnitude, and therefore all moving clocks will be gravitationally slowed down compared to a clock that is at rest with respect to the cosmic rest frame. Similarly, the vector potential will interact with mass currents, and will cause interesting effects like spin precession and phase changes on quantum systems. We will come to those effects later in the paper.

Mathematically, one can start from the Robertson-Walker line element of the homogenous and isotropic Universe.

$$ds^2 = -c^2 dt^2 + \frac{R^2(t)}{1 - kr^2} (dr^2 + r^2 d\Omega^2) \quad (1)$$

Since it is known from observations that the present Universe is nearly flat in spatial sections, $k \simeq 0$. Then the line element is

$$ds^2 = -c^2 dt^2 + R^2(t) (dr^2 + r^2 d\Omega^2) \quad (2)$$

As mentioned earlier $R(t)$ is negligible for time scales of years, and can be approximated as a constant even for extended laboratory experiments. Then we have

$$ds^2 \simeq -c^2 dt^2 + R^2(dr^2 + r^2 d\Omega^2) \quad (3)$$

This is same as Minkowski flat space-time in the special frame (cosmic rest frame) that is at rest with respect to the average Hubble flow. The time coordinate t is an absolute time applicable to all observers at rest with respect to that special cosmic frame, and the CMBR temperature is a monotonic function of t .

It is easy to see that a clock moving relative to the average matter distribution will have a slower rate. We consider a clock in a frame moving with physical velocity $V = R \frac{dr}{dt}$ with respect to the cosmic rest frame. In a frame moving with the clock,

$$ds'^2 = -c^2 dt'^2 \quad (4)$$

The same clock, with reference to the global frame has the interval,

$$ds^2 = -c^2 dt^2 + R^2 dr^2 \quad (5)$$

Considering radial motion for simplicity (any linear motion can be treated this way) and equating the intervals (see later for a proof that the interval is invariant),

$$dt'^2 = dt(1 - V^2/c^2)^{1/2} \quad (6)$$

Since $\int dt$ is the time measured in the global frame, the moving clock advances slower by the factor $(1 - V^2/c^2)^{1/2}$.

Thus a clock moving with respect to the cosmic rest frame records less time compared to a clock that is stationary in the cosmic rest frame. The time dilation is a gravitational effect, and always involves the velocity with respect to a preferred cosmic rest frame. Note that there is no assumption that the motion is uniform and inertial. The expression is applicable to arbitrary motion, with $V = V(t)$.

Our only assumption is that the velocity of light is an absolute fundamental constant in the cosmic rest frame, determined physically by the gravitational interaction of light with the Universe. We will show later that this *implies* the Lorentz transformations and that the velocity of light is a constant in all frames.

It is very important to realize that the effects are gravitational in origin and that in an empty Universe there will not be any relativistic effects, unlike in SR. It is possible to get convinced of this by considering the effect

of the distant galaxies on local physics. One starts by adding up the individual potentials and by calculating the approximate metric, including all matter visible to observational astronomy. This of course does not represent all matter and all of the Universe, but gives a metric that is different from the special relativistic Minkowski metric with metric coefficients that are different from unity by $2\Phi/c^2$, where Φ is the total gravitational potential of all visible galaxies, and $2\Phi/c^2 \ll 1$. The next step is to calculate the effects of moving through this gravitational potential, by using any post-Newtonian framework, or some approximation to General Relativity, for example. *Then one realizes that these are substantial effects not seen in experiments.* Considering only visible matter constituting 5% of the critical density in the Universe, a moving clock has a gravitational time dilation that is 5% of the value predicted by special relativity, relative to a clock stationary with respect to the CMBR. For example, one may calculate the gravitational time dilation effect of the galaxies on a muon circulating in a storage ring for which the measurement of modification of lifetime agrees with the SR prediction to 0.1%. If the gravitational potential due to the galaxies in the cosmic rest frame is designated as Φ_g , we have $\Phi_g/c^2 \simeq 0.05$. In a frame moving at velocity V relative to the cosmic rest frame (CMBR), the potential is

$$\Phi'_g(V) = \Phi_g(1 - V^2/c^2)^{-1/2} \simeq \Phi_g(1 + V^2/2c^2) \quad (7)$$

Therefore the gravitational time dilation of the moving clock relative to the stationary clock will be

$$\Delta T \simeq -\frac{\Phi_g}{c^2} \frac{V^2}{2c^2} \quad (8)$$

With $\Phi_g/c^2 \simeq 0.05$, this is 5% of the special relativistic time dilation, $-V^2/2c^2$. Such a large effect is not seen in any experiment, sensitive typically to 0.1% corrections. Clearly, *there is no room for both the gravitational effect and the special relativistic effect.* Thus, the muon storage ring experiment is already in conflict with SR prediction based on mere kinematics in empty space. One also sees that if one extrapolates the results to include gravitational effects of all matter, integrating upto the Hubble radius, then the physical effects are as large as those seen in experiments, and attributed usually to special relativistic kinematical effects. Since one does not want to conclude that gravitational effects from a visible Universe predict something that is not seen in experiments, the only way out is to admit that all the effects that are attributed to kinematics and SR are indeed the gravitational effects of

the entire Universe, and that SR is an approximate effective description that is applicable in certain special cases of motion (see later). The more fundamental theory – Cosmic Relativity – is based on the gravitational effects of the Universe and it is not limited to reference frames moving with uniform velocity.

2.2 Results for clock comparison experiments

Now I will discuss the time dilation effects within cosmic relativity.

Consider a frame moving at velocity V with respect to the cosmic frame. We consider experiments in which there are clocks moving within this frame, which will be compared among themselves and with other clocks that are at rest within the frame.

Consider a clock within this frame that is moving at velocity u relative to the coordinates inside the frame. The special relativistic time dilation of the clock with respect to a clock that is stationary inside the frame is

$$dt' = dt(1 - \frac{u^2}{c^2})^{1/2} \quad (9)$$

In fact all clocks that move with a speed u relative to the clocks stationary inside the frame will record the same time dilation factor irrespective of the direction of u , according to special relativity. If the clocks are accelerating, the total time dilation is given by

$$\int dt' = \int dt(1 - \frac{u(t)^2}{c^2})^{1/2} \quad (10)$$

In particular if two clocks are moving with velocities $\overrightarrow{u(t)}$ and $-\overrightarrow{u(t)}$ relative to the frame, the time dilation factors of both clocks are identical in Special Relativity. There is no difficulty in dealing with time dilation of noninertial clocks, since the total effect can be calculated by integrating differential effects in instantaneous Lorentz frames that are inertial. SR asserts that no special relativistic time dilation expression should contain the velocity of the frame (with respect to some hypothetical frame in which the moving frame is embedded) in which the experiment is performed.

Just to stress this point I quote from the creator of the theory and the editor who encouraged it.

A. Einstein (1905, [2]): “If one of two synchronous clocks at A is moved in a closed curve with constant velocity until it returns to A, the journey lasting

t seconds, then by the clock that has remained at rest the travelled clock on its arrival at A will be $\frac{1}{2}tv^2/c^2$ second slow". There is no reference to closed curve being noninertial, direction of velocity etc. The velocity in SR refers to the relative velocity.

M. Planck (1909, [3]): "The gist of the principle of relativity is the following. It is in no wise possible to detect the motion of a body relative to empty space; in fact, there is absolutely no physical sense in speaking about such motion. If, therefore, two observers move with uniform but different velocities, then each of the two with the same right may assert that with respect to empty space he is at rest, and there are no physical methods of measurement enabling us to decide in favour of one or the other".

When these were written there was not much knowledge on cosmology or on the average density of the Universe. Since space is not empty, though it is flat, effects that go beyond special relativistic assertions could naturally be expected.

The cosmic gravitational time dilation has the characteristic imprint of the fact that there is a preferred cosmic frame with reference to which the time dilation is calculated. The clock that is stationary within the frame itself has a time dilation with respect to the clocks in the cosmic rest frame. (Such a clock is provided by the temperature of the CMBR). We have to calculate the time dilation of the stationary clock and the moving clock with respect to the cosmic frame (subscript U) and then compare them. For the clock stationary inside the frame (denoted by subscript 0) this is

$$dt_0 = dt_U \left(1 - \frac{V^2}{c^2}\right)^{1/2} \quad (11)$$

and for the moving clock the time dilation (after approximating $(V+u)/(1+Vu/c^2)$ as $V+u$ for $V, u \ll c$, see later) is

$$dt_1 = dt_U \left(1 - \frac{(\vec{V} + \vec{u})^2}{c^2}\right)^{1/2} \quad (12)$$

The time dilation of the moving clock with respect to the reference clock inside the frame then is

$$dt_1 = dt_0 \left(1 - \frac{(\vec{V} + \vec{u})^2}{c^2}\right)^{1/2} / \left(1 - \frac{V^2}{c^2}\right)^{1/2} \quad (13)$$

When both V and u are small compared to c , we get

$$\begin{aligned} dt_1 &= dt_0 \left(1 - \frac{V^2 + u^2 + 2\vec{V} \cdot \vec{u}}{c^2}\right)^{1/2} / \left(1 - \frac{V^2}{c^2}\right)^{1/2} \\ &\simeq dt_0 \left(1 - \frac{u^2 + 2\vec{V} \cdot \vec{u}}{2c^2}\right) \end{aligned} \quad (14)$$

This is drastically different from the special relativistic time dilation by a factor $dt_0(\vec{V} \cdot \vec{u}/c^2)$. The surprising new result is the dependence of the time dilation factor on the velocity of the frame. This is equivalent to considering all velocities relative to the cosmic rest frame or CMBR for calculating the time dilation effect. In SR, no local experiment should have a dependence on the velocity of the frame. Note that it is possible to have the factor $\vec{V} \cdot \vec{u}/c^2$ negative and numerically larger than u^2/c^2 , and therefore it is possible to have a moving clock inside a local frame *age faster* than stationary clock in the same frame, in complete contrast to the special relativistic prediction. Thus, it becomes an issue of experiments to decide which of the two predictions is correct.

(It may be noted that the usual Lorentz transformations of time contain a factor Vx/c^2 , due to the finite velocity of light used in clock synchronizations, which is structurally same as the factor we have derived for time dilation. Therefore, this effect can never be observed in clock comparisons done at a distance, since the effect depends on the direction of travel and cancels out in two-way experiments. But, the effect reveals itself in special experimental situations.)

The expressions above means that if two clocks are compared, one moving with speed u along the direction of $\vec{V}$, and the other with speed u in a direction opposite to $\vec{V}$, there will be a *time asymmetry* when the two clocks are compared *with respect to each other* by an asymmetry factor

$$\eta = \frac{t_1 - t_2}{t_{av}} = \frac{2Vu}{c^2} \quad (15)$$

This multiplied by the duration of the experiment gives the nett time asymmetry. The velocity $\vec{V}$ here is the velocity of the frame with respect to the cosmic frame, and for a laboratory on earth, this will include the rotational, orbital, solar system and galactic velocities. The instantaneous velocity of any laboratory frame on earth's surface is time dependent and it is the vector sum of the different contributions to its velocity – rotational ($R\Omega$), orbital

(V_{orb}), solar system/galactic velocity with respect to the cosmic back ground (V_U) etc. So the total velocity is

$$\vec{V}(t) = R\Omega\hat{\phi} + \vec{V}_{orb} + \vec{V}_U + \dots \quad (16)$$

The time dilation asymmetry is proportional to $\vec{V} \cdot \vec{u}_{clock}$. But, in any experiment where either $\vec{u}$ takes both positive and negative values symmetrically, or all directions with respect to the cosmic frame as in a storage ring for unstable particles, the dot product averages to zero. Therefore, two way experiments in which $\vec{u}$ and $-\vec{u}$ symmetrically occur with $\vec{V}(t)$ not changing direction, as well as storage ring type of experiments on clocks will not see any time dilation asymmetry.

If a clock is taken around the earth along the equator at constant ground speed u , and brought back after a round trip, *its time dilation with respect to a clock stationary on the surface is not given by the special relativistic factor predicted by Einstein in 1905,*

$$\Delta T = -T \frac{u^2}{2c^2} \quad (17)$$

The correct result, according Cosmic Relativity should be

$$\Delta T = -T \left(\frac{u^2}{2c^2} \pm \frac{V_{rot}u}{c^2} \right) \quad (18)$$

The +sign applies when the clock is taken eastwards, along the surface velocity of the earth due to its rotation, and –sign for the trip westwards. All other asymmetry terms are zero. For example the term $\vec{V}_{orb} \cdot \vec{u}$ averages to zero since $\vec{u}$ takes all directions in a round trip along the equator.

Most interestingly, the second term can dominate with a negative sign, and then we get the result that *the clock in motion ages faster than the clock at rest* within the frame. This can never happen in SR.

For a clock moving at ground speed u along the instantaneous surface velocity (440 m/s) of the rotating earth ($V = R\Omega$) with respect to the cosmic frame, and another one moving opposite (eastwards and westwards) the time asymmetry factor is

$$\eta = \frac{2Vu}{c^2} \simeq 10^{-14}u \quad (19)$$

where u is in m/s. If the clocks are taken around in aircraft with a velocity 220 m/s (average ground speed of about 800 km/hour), for about 40 hours

for the round trip, then the predicted asymmetry would be

$$\Delta T = \eta T = \frac{2R\Omega u T}{c^2} \simeq 310 \text{ ns} \quad (20)$$

This is several times larger than the special relativistic time dilation, $\Delta t \simeq -t_{av}u^2/2c^2 \simeq 50 \text{ ns}$.

If an experiment is performed such that the clocks start moving eastwards and westwards around noon (or midnight), then their velocities are parallel and antiparallel to the orbital velocity of the earth around the sun. After a short flight of 1 hour the Cosmic Relativity predicts a time asymmetry of a whopping 720 ns, for a ground speed of 220 m/s. But for a neat comparison we need to bring the clocks back. This will cancel the effect, and therefore the comparison has to be done at a distance. This is not possible since synchronizing clocks at a distance will contain the same terms we are trying to detect, and therefore the only way such experiments can be done is by bringing the clocks back in a round trip around the earth in a constant speed orbit.

Though not obvious from the way we started our analysis, a look at the expression for ΔT indicate that the total time dilation asymmetry depends only on the product uT , which is just the total path length covered in the experiment. It does not matter how fast the clocks are moved, provided we move them by the same distance. Slow transport will need more time, and the asymmetry depends only the product of the velocity and duration. Thus if the clocks are taken around by *walking around the earth* eastwards and westwards along equator, the clocks will show an asymmetry that is exactly equal to the one predicted for clocks taken around in fast flights! The only requirement for a good measurement is that the clocks be stable over a long time. In contrast the special relativistic time dilation that is quadratic in the velocity will be negligible for the slowly transported clocks. For example, at a transport velocity of 1 m/s, around the earth, the special relativistic time dilation is only a fraction of a nanosecond, whereas the time dilation asymmetry between the two clocks is still about 310 ns.

There is strong and unambiguous evidence for the gravitational effect of the Universe, or for the validity of Cosmic Relativity, from earlier clock comparison experiments.

Figure 1: Round trip clock comparison

3 Experimental evidence for Cosmic Relativity

As I have explained in earlier sections, we need to look at an experiment in which the term $\vec{V} \cdot \vec{u}_{clock}$ does not average to zero to test whether the correct theory is SR or CR. One of the classic tests of SR with clocks is the modification of the lifetime of unstable particles like muons when they move at large velocity. In cosmic ray experiments, the accuracy of lifetime measurement is not better than a percent or so, and usually there is averaging over all directions. Thus the asymmetry term averages to zero. A more precise experiment (0.1%) is the lifetime measurement of muons in a storage ring. But, again the asymmetry term averages to zero, since the muon velocity takes all directions in the storage ring with respect to the velocity of the earth in the cosmic frame. I have already mentioned how this measurement indicates a conflict between gravitational physics and SR.

It turns out that (apart from GPS whose precision data is not publicly available) there are only two experiments with enough accuracy that can throw light on the question we are discussing. I will discuss the famous clock comparison experiment by Hafele and Keating in 1971-72 [4]. Later clock comparison experiments with higher precision [5] confirm these observations.

Hafele and Keating flew four clocks in commercial aircraft around the earth, one set eastwards and another westwards. When they reached back, they were *compared with a clock stationary on earth's surface*. The transported clocks read times different from that of the stationary clock as expected, but in addition the transported clocks also showed a large time asymmetry between them. The average total duration of the round trip was about 45 hours. The clock that was transported westwards was found to be advanced ('older') with respect to the stationary clock, and the others that flew eastwards were found to be retarded ('younger'). When compared with the stationary clock, one has to take into account of the gravitational redshift due to the fact that the aircraft clocks are at a different distance from the earth's centre compared to the one on the surface and there is a large gravitational time dilation. The flight clocks will run faster than the surface clocks by about 150 ns for the parameters of the experiment due to the gravitational effect of the earth. Special relativistic time dilation predicts that the flight clocks will run slower by about 50 ns after the flight. Both these effects are symmetrical for the two clocks in flight. Yet, Hafele and Keating found that one clock gained time whereas the other lost compared to the stationary clock.

The details of the flights were as follows:

The eastward flight lasted 41 hours, and the calculated gravitational effect in earth's field is faster aging by 144 ns relative to the surface clock. The westward flight lasted 49 hours, and the gravitational effect is 179 ns. Special relativistic effect calculated using the prescription in Einstein's original paper, $\Delta t \simeq -tv^2/2c^2$, is -36 ns for the eastward clock and -45 ns for the westward clock, the 20% difference coming from the 20% difference in flight times. So, the expected time difference relative to the stationary clock at earth's surface is 108 ns for the eastward clock and 134 ns for the westward clock, with about 20% errors in estimation. The observed time differences were -59 ns eastwards, and $+273$ ns westwards. After subtracting out the gravitational effects in the earth's field, it is found that the clock that travelled eastwards aged less relative to the surface clock by about 203 ns, and the clock that travelled westwards *aged more relative to the stationary clock* by as much as 94 ns. *Both these numbers are very different from the prediction of aging less by about 40 ns, calculated as in Einstein's 1905 paper.* The 'travelled clock aging more than the stationary clock' contradicts the special relativistic prediction. Significantly, these numbers agree within errors (20% in estimates of flight parameters and 10% in experimental data) with what

one would expect if one clock travelled at a velocity of about 660 m/s for 41 hours and another at velocity of about 220 m/s for 49 hours, while the reference clock itself travelled at a velocity of about 440 m/s (linear velocity of the earth's surface during flight take-off), relative to the cosmic rest frame.

It is important to note that the reference clock on the earth's surface is irrelevant for the analysis of the time dilation asymmetry between the two clocks. For a direct comparison of the clocks in flights, the clocks on earth's surface does not come into picture. The two clocks in flights execute nearly symmetrical motion with respect to each other, and when they are compared with each other, there should not be any asymmetry between them according to SR. But an asymmetry of about 300 ns was found between the two clocks.

The authors unfortunately went through an inconsistent analysis of their data to establish that Special Relativity was valid [4, 6]. They argued that they should not compare their moving clocks with the clock stationary on earth's surface because such a clock would not obey SR due to its noninertial motion. They denied the applicability of instantaneous Lorentz transformations on clocks moving with constant speed, with a continuous change in the direction of velocity. They calculated the expected effect by comparing the clocks in aircraft, and the stationary clock on earth with a hypothetical clock that is moving with the center of mass motion of earth, but nonrotating with respect to the cosmic frame. Equivalently, they went to a cosmic frame (see later) and compared all clocks exactly as in Cosmic Relativity. Though they did go to an external super-frame to use 'inertial reference clocks', the clocks in the aircraft, which executed motion very similar to the clock on the earth was treated as clocks obeying SR – a surprising and obvious inconsistency. Thus they used the argument that clocks on earth's surface were noninertial and not good as reference, but ignored that consistency demands that the clocks that are to be compared also have to obey the same criterion by SR. The fact of correct physics is that there is no need to go to the external hypothetical frame in SR. It has been established in particle accelerator experiments that the noninertial nature from circular motion is not a problem in applying Lorentz transformation equations. Lorentz transformation can be used in accelerating and rotating frames, by using instantaneous Lorentz frames and then integrating the effect. Thus, an asymmetry will be observed only if Special Relativity is not the correct theory of time dilation.

Let us list the reasons why the Hafele-Keating analysis is inconsistent and their claim of having verified special relativity is incorrect:

1. The two clocks in flight execute identical motions *relative to each other*. Therefore, they should not show any time asymmetry with respect to each other in SR. Such an asymmetry is a prediction of Cosmic Relativity. The observed *asymmetry* is independent of whether it is obtained by comparing with clocks on earth's surface, or with some hypothetical clocks that are nonrotating, or *without considering any other reference clocks*, invalidating the entire reasoning given by Hafele and Keating for establishing validity of SR.
2. In SR, there is clear prediction that if the clock is moved in whatever way with respect to a stationary clock, whether in an inertial or noninertial frame (again using instantaneous Lorentz frames) the clock that is moving will *always slow down with respect to the stationary clock*. This is precisely the prediction in Einstein's original paper. There is no way in special relativity that it will age more than a stationary clock. But Hafele-Keating result shows that this happens. Such an effect is the prediction of Cosmic Relativity.
3. The clocks can be compared by taking them around at very slow speeds, and the time dilation asymmetry will remain the same. The special relativistic time dilation, quadratically dependent on the velocity, can be made negligible by moving slow.
4. The experiment actually compared the real noninertial clocks in flights with the real noninertial clocks on earth, and not with inertial hypothetical clocks. So, bringing in inertial hypothetical clocks as *essential* intermediaries for calculation points to the presence of the cosmic gravitational effects and to the inadequacy of SR.
5. Suppose the earth was neither rotating nor moving in the solar system. The two flight going eastwards and westwards at the same ground speeds have identical and symmetrical circular paths with respect to each other. Therefore there cannot be any time asymmetry between them. The relative aging of the two clocks when they are compared should be an invariant physical fact. If we observe this situation from an external rotating frame, rotating at the angular velocity of the earth, then we have the Hafele-Keating situation. According to SR such a common rotational velocity should not change any result on clock comparisons. But there is a real physical difference in the Machian sense,

between the earth and the flights rotating together with respect to the preferred rest frame and gravitational configuration of the cosmos, and a situation where these are not rotating, but the observer is rotating. There will be a corresponding difference in physical effects in Cosmic Relativity.

6. Finally we note that no relativist analyzes the standard twin-clock problem in SR by going to the preferred cosmic frame encompassing the two twins' motion, though it is clear that choosing such a frame in which the stationary twin is 'absolutely' stationary and the travelling twin is in motion relative to the cosmos immediately gives the result that the travelling twin ages less than the stationary twin. Nobody does it this way because choosing such a frame denies and discredits SR, and implies that the motion should be analyzed from a frame in which the concepts 'stationary' and 'moving' has absolute sense. But Hafele and Keating did exactly this. Once you go out of the local frame to a super frame (the nonrotating absolute frame), one of their clocks move faster than the other, in an absolute sense, during the round trip. But this is Cosmic Relativity and not Special Relativity.

Hafele and Keating observed a time dilation asymmetry of 332 ns with a statistical uncertainty of less than 4%. The observed asymmetry matches well with the time asymmetry predicted by Cosmic Relativity.

Thus there is no doubt that the result observed by Hafele and Keating is due to the gravitational effect of the Universe on moving clocks and not due to kinematics of relative motion as described by special relativity [7].

Similar evidence will be present in GPS data. The correct synchronization of these clocks to good precision will have to use results from Cosmic Relativity presented here. What is usually called the Sagnac term in this context is the gravitational effect of the Universe. This will be true also for the planned European satellite and clock network.

4 New tests of Cosmic Relativity

Though we expect modification of all physical measures like time, length, mass etc., due to gravitational effects of the Universe, the best experiments for a precision test are clock comparison experiments.

Figure 2: Analyzing this experiment reveals the inconsistency and inadequacy of Special Relativity

A new experiment that repeats the Hafele-Keating experiment with an improvement of precision from 10% to 1% is certainly very important. But, that is a tedious experiment and the effect is not large since the only frame velocity that contributes to the time dilation asymmetry is the rotational velocity of the earth's surface, 440 m/s. But, as mentioned earlier, the gravitational effects we are discussing are universal and any scheme of comparing or synchronizing clocks at a distance will have the asymmetry term relevant for the separation of the clocks (Vx/c^2), and the only clean way of doing an experiment is to depend on the round trip comparison. Therefore we clarify certain issues in round trip comparison experiments to unambiguously show that the only consistent interpretation of the Hafele-Keating type experiment and also the original twin clock problem is possible only within Cosmic Relativity and not in Special Relativity.

4.1 Analysis of a variation of the Hafele-Keating experiment and proof for the validity of Cosmic Relativity

Consider the race-track clock comparison experiment depicted in figure 2.

The experiment is done such that most of the motion of both the clocks are straight inertial trajectories. The only portions where there are noninertial motions are at the regions A and B. The clocks are transported at equal ground speeds, v_g , relative to the track surface, and the track itself is like a conveyor belt of total length L , moving at velocity v_t . The clocks start

from the same point, go around and come back and meet at the starting point after the round trips. Since the clocks come back and compare the entire flight data there is no consistent way to include fictitious gravitational fields into the problem since the two clocks will never consistently agree on such fictitious fields. The SR calculation for each clock now gives nearly identical time dilations and the only differences, if at all, could be due to physical effects at the regions where there is noninertial motion. But, the contribution from these regions can be made arbitrarily small by making the linear portion of the race-track long enough (or by keeping the clock readings frozen during accelerated motion). The prediction from Cosmic Relativity for the time asymmetry between the two clocks however is proportional to the sum of the length of the round trip trajectories for the two clocks,

$$\Delta T = \frac{2\vec{V} \cdot \vec{u}T}{c^2} = \frac{2v_t L}{c^2} \quad (21)$$

Also, one of the ‘travelled clock’ can age more relative to the ‘stationary clock’, when the velocity of the race-track belt relative to the cosmic rest frame is more than the velocities of the clock relative to the track. There is no way to get this result in SR without invoking absolute velocities with respect to the preferred frame of the cosmos. More importantly, the time asymmetry between the clocks cannot be attributed to any pseudo-potential or noninertial features since the effect is dominated by motion in the inertial regime. In the limit of the linear portion of the race track shrinking to zero, we get the Hafele-Keating situation with $v_t = R\Omega$, and then the time asymmetry is

$$\Delta T = \frac{2R\Omega \times 2\pi R}{c^2} = \frac{4\pi R^2\Omega}{c^2} \quad (22)$$

So, the asymmetry in the clocks is not physically related to noninertial motion, since in the general case the effect is proportional to the path length traversed in total during inertial and noninertial motion. The entire effect is due to the gravitational interaction with the Universe as predicted by CR. This result justifies well the validity of Cosmic Relativity.

4.2 The Sagnac Effect

The Sagnac effect was first discovered in optical interferometry. The phase shift in a rotating planar interferometer with area A , in which light travels

in two opposite paths and return to their starting point is given by

$$\Delta\varphi = \frac{4A\Omega\omega}{c^2} \quad (23)$$

ω is the angular frequency of light, and Ω is the angular velocity of rotation.

This expression is same as the expression for the time asymmetry in round trip clock comparisons, since $\Delta\varphi = \omega\Delta T$, and

$$\Delta T = \frac{4\pi R^2\Omega}{c^2} = \frac{4A\Omega}{c^2} \quad (24)$$

It is implied that the physical interaction responsible for the Sagnac effect is the gravity of the Universe. We will discuss this in detail in another paper [8]. Here we merely note that the total equivalence of the expression for the Sagnac effect for light and matter waves arises from the fact that gravitational interaction is universal, and therefore the *Sagnac effect does not depend on the group velocity of waves* used in Sagnac interferometry (this result is not intuitively obvious, for example in a Sagnac interferometer that uses optical fibers, since the light pulse takes more time to circle around and yet the time difference between the clockwise and counterclockwise pulses is still given by the same equation.) This result can be derived simply in CR as the phase change on waves due to the vector potential generated due to motion with respect to the universe. The expression is same as in electrodynamics.

$$\Delta\varphi = \frac{E}{\hbar c^2} \oint \vec{A}_g \cdot d\vec{l} \quad (25)$$

where E is the energy of the interfering entity ($\hbar\omega$ for light) [8].

4.3 The inconsistency in SR

I have already shown that there is evidence against SR from the Hafele-Keating experiment, and even from other ‘relativistic’ experiments done in the ever present gravity of the Universe. While SR is a correct effective description of phenomena in a limited domain, there are situations accessible to experiments where SR has no consistent answer. Another example that is very instructive is that of the original twin clock problem or the twin paradox. While many physicists will be dismissive about any new discussion on this issue, anybody who has attempted to calculate the proper time in the frame

of the travelling twin will realize immediately that there is a problem and that there is no consistent answer within SR.

In the frame of the stationary twin, the answer from SR and Cosmic Relativity are identical.

The proper time for the stationary twin is given by

$$T_1 = \int g_{00}^{1/2} dt = \int dt \quad (26)$$

since the corresponding clock is at rest. In the frame of the second twin, his proper time in SR is given by two parts, one corresponding to the part of the journey that is inertial, and another part where the metric is different due to noninertial accelerations generated for turning back.

$$T_2 = \oint g_{00}^{1/2}(t) dt = 2 \int_I dt + 2 \int_{NI} g_{00}^{1/2} dt \quad (27)$$

There is no way to estimate the second term in SR since local measurements within the frame give only the value of the acceleration. So, even if it is equated to a pseudo-gravitational field, the gravitational potential and the local metric are not determined, unless one takes the rest frame of the cosmos as the reference. In any case, whatever the contribution from that term is, it can be made *arbitrarily small compared to the first term* by making the inertial leg of the journey longer and longer. So, the proper time calculated in both frames becomes approximately equal within SR. Or, rather trivially, the clock can be made to work only during the linear inertial leg of the journey, ‘frozen’ during accelerations, and finally compared after returning, and then SR has no consistent and correct answer. Note that the experiment can be designed such that the clock is made to work only during the outward inertial journey, and frozen in reading and brought back, and still have a time dilation relative to the stationary clock, always correctly predicted in Cosmic Relativity, but never consistently given in SR. In such an experiment, SR allows either clock to be treated as at rest during the inertial first part of the journey, and has no unambiguous prediction for the time dilation. But Cosmic Relativity predicts that the clock that travelled relative to the cosmos ages less compared to the one that did not, without any ambiguity.

In Cosmic Relativity, the metric for twin 1 is $g_{00} = 1$, and for the twin 2 it is $g_{00} = (1 - V^2/c^2)$, where V is the velocity with respect to the cosmic frame as determined by the dipole anisotropy in the CMBR in the frame of

Figure 3: A variation of the twin clock problem.

twin 2. The effect during turn around is unimportant when the duration of the uniform motion is long enough. Thus, the travelling twin ages slower due to the gravitational effect of the Universe during inertial motion through the cosmos.

This analysis suggests that Cosmic Relativity is the only consistent theory of relativity in flat space and time. SR that is based on kinematical effects in relative motion fails in situations where comparison can be made after round trips, with a major fraction of the round trip executed as inertial motion. In such situations pseudo-potentials do not come to rescue since the non-inertial contributions can be made arbitrarily small. Noninertial motion is treated the same way as inertial motion in Cosmic Relativity.

Thus Cosmic Relativity is the generalized theory of relativity in flat space-time, since it does not distinguish between inertial and noninertial motion.

5 Cosmic Relativity and physical effects in quantum systems

There are several important physical effects predicted by Cosmic Relativity, all of which are manifestations of the gravitational interaction of the physical system with the Universe. Two important effects we consider are the spin precession in atoms and the phase changes in quantum systems that are moving in the cosmos. Our results can be considered as the generalization of the Machian idea to quantum systems. However, instead of starting from

the Mach's principle, we start from cosmology and relativity. For a critical Universe, it turns out that the result on spin precession for a full orbit is identical to the Thomas precession. We have identified the physical interaction responsible for the Thomas precession – it is the gravitational interaction with the Universe [9]. Thus part of the fine structure splitting in atoms is due to the ever present gravitational interaction of the orbital electrons with the massive Universe.

Consideration of phase changes of quantum systems yields a surprising and pleasing result. The connection between spin and statistics in quantum theory could be a consequence of the gravitational interaction of the spin with the Universe. The interaction is gravitomagnetic in nature, and gives us the result that identical integer spin particles obey Bose-Einstein statistics and identical half-integer spin particles obey Fermi-Dirac statistics [10]. This is a deep result, and for the first time might answer the long-standing query – what is the physical reasons behind the spin-statistics connection? It also answers why the connection is valid in non-relativistic, two-particle situations despite the general impression that it is a consequence of relativistic field theory.

5.1 The spin precession in atoms and the fine structure

It is perhaps not surprising that Cosmic Relativity will give the correct spin-precession for electrons in atoms when we consider motion in a critical Universe. As in the case of the muons in storage ring, the numerical results from Cosmic Relativity matches the known results from SR in this case, for a critical Universe. The available high precision data leave no room for both kinematical effects and gravitational effects to be present together. Therefore, since massive galaxies exist, we have to conclude that the observed effects are indeed due to the gravitational effects of the Universe.

When the idea of electron spin was first proposed by Uhlenbeck and Goudsmit, they had not resolved the problem that the simple L-S coupling gives twice the experimentally observed value for the fine structure splitting. It is only after Thomas derived the special relativistic Thomas precession [11] that things were set right (Though Kronig seems to have worked out the correct relativistic expression earlier). The basic idea behind the Thomas precession is that two Lorentz boosts in different directions are equivalent to a boost and a rotation, and that this rotation is responsible for the precession of the spin.

In Cosmic Relativity, the electron that is moving in the cosmic gravitational potential ϕ of the Universe experiences a modified gravitational potential and a vector gravitational potential equal to

$$\phi' = \phi(1 - V^2/c^2)^{-1/2} \quad (28)$$

$$A_i \simeq \phi \frac{V_i}{c} (1 - V^2/c^2)^{-1/2} \quad (29)$$

Circular motion then gives a nonzero curl for the velocity field, and this is a gravitomagnetic field due to the entire Universe. This gravitomagnetic field couples to the spin angular momentum. Also, the modified potential modifies precession rate of spin and this is exactly the Thomas precession [9].

Thus we are able to identify the physical torque that is responsible for the *physical* precession of the spin, instead of attributing it to a kinematical effect. It is certainly more satisfactory to identify a physical cause for a physical change than to stop at a description of the physical change. Since the Thomas precession term is usually written as

$$\omega_T = \frac{\mathbf{v} \times \mathbf{a}}{2c^2} \quad (30)$$

where $\mathbf{v}$ is the velocity and $\mathbf{a}$ the *centrifugal acceleration* in the orbit, it may be guessed that the term has something to do with the gravitational interaction with the Universe. The fictitious forces normally attributed to kinematics are in fact due to the gravitational effect of the Universe [12]. This effect is identical for a classical gyroscope and a quantum spin, when we consider expectation values. This is because the gravitational effects are universal, and just as the gravitational acceleration is independent of the mass, the spin precession is independent of the value of the spin itself. Experiments like Gravity Probe-B seek to measure spin precession effect arising from a similar term in the gravitational field $\mathbf{g}$ of the earth,

$$\omega_g = \frac{\mathbf{v} \times \mathbf{g}}{2c^2} \quad (31)$$

where, $\mathbf{v}$ is the velocity of the gyroscope through the Newtonian gravitational field. Therefore, the only connections we need to realize that the Thomas precession is due to the gravity of the Universe is the Machian assertion that centrifugal forces in all situations arise due to the interaction with the massive Universe, and the equivalence principle that guarantees local equivalence of $\mathbf{g}$ and $\mathbf{a}$ [13].

More explicitly, since the Thomas precession frequency for the nearly circular orbit can be written as

$$\omega_T = \frac{\mathbf{v} \times \mathbf{a}}{2c^2} = -\frac{\Omega v^2}{2c^2} \quad (32)$$

it is clear that the term arises in the gravitational interaction of the spin with the curl of the vector potential generated in moving through the critical Universe,

$$\nabla \times \mathbf{A} \simeq \Omega(1 - v^2/c^2)^{-1/2} \quad (33)$$

In the quantum treatment of this problem, the gravitational contribution to the fine structure splitting is due to the quantized, two-valued coupling energy between the quantum spin and the gravitomagnetic field of the Universe generated by the orbital motion of the electron in the gravitational field of the Universe. Thus, there is no need to invoke a classical torque acting on a classical model of a spin.

Since the galaxies and massive Universe exist, the Dirac equation for the electron should contain an additional term in the Hamiltonian that represents the gravitational interaction of the electron with the Universe. As soon as this term is included, gravitational effects of the type we discussed in this section will be seen to emerge, including the correct Thomas precession term. As I stressed earlier, precision experimental data do not allow both a kinematical contribution from SR in empty space as well as the gravitational effects from the Universe to be present together. The only possible physical choice is to conclude that all measured relativistic effects are due to the gravitational interaction with the Universe.

Thus, fine structure spectroscopy is the most precise measurement of whether the Universe is evolving at the critical density [9].

5.2 Gravity and the spin-statistics connection

The spin-statistics connection in quantum mechanics is a very intriguing fact. While there is no physical understanding of the connection, mathematical proofs invoking field theoretic reasoning exist. The proof by Pauli used the mathematical fact that the quantization of the field of integer spin particles is associated with commutator relations and the quantization of half-integer spin particles is associated with anti-commutator relations between operators, and these coupled with requirements from Lorentz invariance provided

the proof [14]. Later, there have been other attempts to provide simple proofs, and the general assessment seems to be that there is no simple proof, let alone a physical understanding of the connection.

First we state the spin-statistics connection:

a) Particles with integer spin are bosons and they obey the Bose-Einstein statistics.

b) Particles with half-integer spin are fermions and they obey the Fermi-Dirac statistics.

Equivalently (as normally attempted in proofs),

a) The amplitude for a scattering event between identical integer spin particles and the amplitude with an exchange of the particles add with a plus (+) sign. In other words, the phase difference between the scattering amplitude and the exchanged amplitude is an integer multiple of 2π .

b) The amplitude for a scattering event between identical half-integer spin particles and the amplitude with an exchange of the particles add with a minus (−) sign. In other words, the phase difference between the scattering amplitude and the exchanged amplitude is an odd integer multiple of π .

A geometric understanding of these statements was published by Berry and Robbins [15], and several authors have invoked the relation between rotation operators and exchange of particles in quantum mechanics to prove the spin-statistic theorem [16]. Sudarshan has been arguing for the existence of a simple proof that is free of arguments specific to relativistic quantum field theory[17]. While these attempts have clarified several issues regarding the connection, none provides a good physical understanding of the connection.

It may be noted that physically the connection is applicable for any two identical particles, in non-relativistic quantum mechanics. Thus we should expect that the physical proof need not depend on relativistic quantum field theory.

In what follows, we suggest that *it is the gravitational interaction of the quantum particles with the entire Universe that is responsible for the spin-statistics connection* [10]. In other words, the Pauli exclusion is a consequence of the relativistic gravitational interaction with the critical Universe, which is always present.

Consider the scattering of two identical particles, Fig. 4.

The upper event can happen by two quantum amplitudes, shown in the lower panel. The amplitudes for these two processes differ by only a phase for identical particles in identical states, since the two processes are indistinguishable. The particles are assumed to be spin polarized in identical

Figure 4: Amplitudes for scattering between indistinguishable particles

directions, perpendicular the plane containing the scattering event. Only then, the initial and final states are indistinguishable. We can calculate the phase changes in any configuration, but at present we want to discuss only the phase difference for indistinguishable states.

First we note that the two processes are different in the angle through which the *momentum vector* of the particles turn in the scattering process. In fact that is the only difference between the two amplitudes. The difference in angles is just π . (This is why it is equivalent to an exchange - what is really exchanged is the momentum vector after the scattering). We note the important fact that the entire process happens always in the gravitational field of the entire Universe.

The calculation for each particle can be done by noting that the k -vector can be considered without deflection, but the entire Universe turned through an appropriate angle, with angular velocity of this turning decided by the rate of turning of the k -vector. It does not matter whether we are dealing with massless particles or massive particles since the only physical fact used is the change in the direction of the k -vector of the particle.

As discussed earlier, the motion of the particle relative to the Universe generates the vector potential, and the rotation of the momentum vector

generates a nonzero curl and therefore a gravitomagnetic field,

$$A_i \simeq \phi \frac{V_i}{c} (1 - V^2/c^2)^{-1/2}$$

$$\vec{B}_g = \nabla \times \mathbf{A} \simeq \vec{\Omega} (1 - v^2/c^2)^{-1/2} \quad (34)$$

where $\vec{\Omega}$ is the rate of rotation of the k -vector. If we start this calculation from the Robertson-Walker metric, then what is relevant is the curl of the vector potential which is just $\nabla \times \vec{v}$ for a critical Universe. This field acts on the particle only for the duration of the turning of the k -vector, and causes no forces for a point particle. However, it can cause both spin-precession and phase changes in a quantum particle. The spin-gravitomagnetic field interaction energy is $\mathbf{s} \cdot \vec{\Omega} (1 - v^2/c^2)^{-1/2}$. (This is what is responsible for the contribution to the fine structure splitting in atoms). The phase change in the state of each particle is given by the product of the duration of interaction and the spin-gravitomagnetic interaction energy,

$$\varphi = \mathbf{s} \cdot \vec{\Omega} (1 - v^2/c^2)^{-1/2} \times t (1 - v^2/c^2)^{1/2} = s\theta \quad (35)$$

where θ is the angle through which the k -vector has turned in the scattering process. The Lorentz factor correction to the vector potential does not affect the final phase since it is the product of the gravitomagnetic field and the time duration of interaction; the Lorentz factors cancel out. Note that this is a gravitational phase shift, which involves all the fundamental constants G , c and $\hbar$. These constant are hidden from the final expression because $\sum_i Gm_i/c^2 r_i = 1$ in a critical Universe. When the density is not critical, these constants will appear explicitly in the expression for this phase change. Also note that this phase difference is an unambiguous prediction from relativistic gravity in flat space, in a Universe with critical density.

The momentum vectors turn in the same sense for both the particles and therefore the total phase change is $\varphi_1 = 2s\theta_1$ where θ_1 is the angle through which the k -vector turns for the first amplitude. For the second amplitude the phase change is

$$\varphi_2 = 2s\theta_2 \quad (36)$$

The phase difference between the two amplitudes is

$$\Delta\varphi = 2s(\theta_1 - \theta_2) = 2s \times \pi \quad (37)$$

The rest of the proof of the spin-statistics connection is easy. For zero-spin particles the proof is trivial since

$$\Delta\varphi = s(\theta_1 - \theta_2) = 0 \times 2\pi = 0 \quad (38)$$

and therefore zero-spin particles are bosons and their scattering amplitudes add with a + sign. Zero-spin particles have no spin-coupling to the gravitomagnetic field of the Universe and there is no phase difference between the two possible amplitudes in scattering, and they behave as bosons. What remains is the proof for spin-half particles, since the higher spin cases can be constructed from spin-half using the Schwinger construction. The only case to be treated when dealing with identical, indistinguishable states of spin is the one in which the spins are identically pointing, perpendicular to the plane containing the k -vectors. The phase angle difference between the two amplitudes then is

$$\Delta\varphi = 2s(\theta_1 - \theta_2) = 2 \times \frac{1}{2} \times \pi = \pi \quad (39)$$

The relative phase is $\exp(i\pi) = -1$. The amplitudes add with a negative sign. Therefore, the half-integer spin particles obey the Pauli exclusion and the Fermi-Dirac statistics.

Our proof reproduces the result that exchanges of *any* two particles in a multiparticle system of identical fermions introduces a minus (−) sign between the original amplitude and the exchanged amplitude.

It is interesting to note that the proof is valid for interacting particles since the phase changes due to interactions are identical for the two amplitudes, as all other dynamical phases in the relevant diagrams.

This remarkable connection between quantum physics and gravity is indeed startling. It is also very satisfactory physically since it is reasonable to expect that a deep physical phenomenon is linked to a physical cause or interaction and not just to mathematical structures and consistency. Most importantly, as I always stress, the massive Universe exists, and the gravitational phase difference between the two amplitudes is physically unavoidable. If gravity is a long range interaction and if our understanding of classical gravity is more or less correct, then these phase changes are direct consequences.

Many of the measured geometric phases on particles with spin, when they are taken around trajectories in space with their momentum vector turning in space, are of the same nature. Those geometric phases are simply given

by

$$\varphi = \oint s d\theta \quad (40)$$

where $\int$ mean an integral over the entire trajectory with appropriate signs. This clarifies to some extent the relation between our proof and the discussion by Berry and Robbins. It also clarifies why the proofs that depend on rotational properties of wavefunctions have some success.

5.3 Cosmic Relativity and Electrodynamics

Static electromagnetic fields are modified by the gravitational potentials in a laboratory moving relative to the cosmic rest frame. Detailed considerations indicate a satisfactory description of phenomena like the unipolar induction and its variations. There is no satisfactory description of such phenomena within special relativity, especially since these seemingly counter intuitive and asymmetrically relativistic phenomena occur in non-inertial situations. My conclusion is that the gravity of the universe is the underlying interaction that is responsible for the peculiar observations related to unipolar induction. I will discuss these aspects in detail, along with some experimental results and ideas, in separate papers [18, 19, 20].

6 Principle of Cosmic Relativity

Now I outline systematically the fundamental principle of Cosmic Relativity, its relation to Lorentzian and Einsteinian relativity, and the intimate connection to cosmology. While Lorentzian Relativity's transformation equations are identical to the ones in Cosmic Relativity, the physical effects are due to gravity in Cosmic Relativity and there is no ether. The entire structure of Cosmic Relativity is based on flat space cosmology, as always 'given'. Thus, every physical effect that was tested as a special relativistic effect was in fact the result from Cosmic Relativity, due to the gravitational action of the entire Universe.

6.1 The fundamental principle regarding the velocity of light

The fundamental principle of Cosmic Relativity is that the velocity of light is a fundamental constant determined by the local average gravitational potential due to the entire Universe in the cosmic rest frame. (While I treat this as an assumption of the theory, the restriction of velocities by the gravitational potential can be derived once self-consistency is demanded. Gravity of the Universe generates a phase drag on anything moving through the Universe and limits the maximum possible velocity. See later). This is enough to deduce that it is a constant in all frames. In SR, the constancy of velocity of light in all frames is an assumption, whereas in Cosmic Relativity it follows from the fact that it is constant in one special frame that *encompasses all frames within it*.

Since the cosmic rest frame encompasses everything moving within it, it is clear that light emitted from a moving source will still have the same velocity c , irrespective of the state of motion of the source. Thus identifying the preferred frame as the cosmic rest frame itself easily accounts for the counterintuitive fact that the velocity of the source does not affect the velocity of light emitted from it. This immediately implies that the velocity of light measured in any moving frame also has to be an invariant, c . To see this, consider light emitted by any source outside the frame (Fig. 5) entering a frame moving in the same direction with velocity $\vec{v}$. The velocity of this light relative to the cosmic frame is of course $\vec{c}$. If the apparent velocity of light inside the observer's frame moving at velocity $\vec{v}$ is $\vec{c} - \vec{v}$ then there will be a contradiction. The observer can deflect the light in any direction inside his frame with a mirror stationary in his frame, thus changing the direction of light without modifying its speed inside his frame. But now, the speed of light relative to the cosmic frame will not be c . When the light is reflected back from a stationary mirror, the apparent velocity inside the frame is $-(\vec{c} - \vec{v})$. Then the velocity with respect to the cosmic frame should be $-(\vec{c} - \vec{v}) + \vec{v} = -(\vec{c} - 2\vec{v})$ instead of $-\vec{c}$. Therefore we can see that the existence of the absolute cosmic rest frame, and the requirement that the velocity of light in that frame is a fundamental constant imply that it is constant in all frames. In Cosmic Relativity the numerical value is uniquely determined, and it is equal to the average gravitational potential of the Universe at critical density.

Figure 5: Relation between velocities in cosmic rest frame and moving frame if the velocity of light were dependent on the velocity of the frame.

From this it follows that the transformation equations connecting the cosmic rest frame and any other frame moving within the Universe are the Lorentz transformations. Lorentz transformations ensure that the velocity of light is the same constant c if measured in all frames. We do not have to assume the constancy of velocity of light in all frames – it follows from the fact that the preferred frame encompasses all frames and observers. This is a remarkable conceptual advantage of Cosmic Relativity over Special Relativity, apart from its better agreement with cosmology and experimental facts. For the consistency of the Lorentz transformations it follows that c is also the maximum velocity that can be reached from any velocity less than c by acceleration (I will address the issue of Tachyons elsewhere).

Since the transformation equations connecting the cosmic rest frame and any other frame S moving at velocity V is the Lorentz transformation, the standard velocity addition formula follows for the resultant velocity of a second frame S' moving with velocity u relative to the first frame. The velocity of the frame S' with respect to the cosmic rest frame when V and u are in the same direction is

$$U = \frac{V + u}{1 + Vu/c^2} \quad (41)$$

Of course, this is approximately $V + u$ when $V, u \ll c$, and we used this approximation in the calculation of the clock comparison expressions.

6.1.1 Universal gravity is the velocity limiting agency

It is often asked what is the physical reason for a maximal velocity for any entity in this Universe. The answer is available within Cosmic Relativity. It is the gravity of the Universe that determines the numerical value of the velocity of light, and it obeys the relation

$$|\phi_U| = c^2 \quad (42)$$

In Cosmic Relativity, this is seen as a phase drag (not a force) due to the gravitational potentials on any entity moving through the Universe. Surprisingly, this view is consistent only if every material entity with a gravitational interaction has also wave property and ‘phase’ associated with it. If the Universe were empty, the velocity of light would be infinite. The actual numerical value is determined self-consistently; if we start by assuming a large velocity, then the effective gravitational potential is larger due to a larger causally connected Universe. More the gravity, more the constraining effect on the phase advance of the light or any other entity. Since the gravitational coupling is universal the restriction applies to light as well as everything else.

6.1.2 Why is $E=mc^2$?

I have already mentioned the important physical relation between the velocity of light and the average gravitational potential of the Universe at any point. For the Universe at critical density,

$$|\phi_U| = c^2$$

It is worth commenting on this relation. If the Universe started from pure nothingness, then it is expected that every constituent of this Universe has zero energy. One part of the energy is the gravitational interaction energy given by $E_g = -m\phi_U$. Clearly, every mass at rest with respect to the cosmic frame should possess an energy, positive and equal to E_g to be consistent with its origin from void. Thus we expect that in a massive Universe all masses possess a rest energy equal to $E_0 = m|\phi_U|$. We write $E_0 = \kappa mc^2$, since $|\phi_U|$ has dimensions of velocity and κ is related to the matter density of the Universe. For critical Universe we know that $|\phi_U|/c^2 = 1$, and thus $E_0 = mc^2$.

6.1.3 The classical Equivalence Principle

It is appropriate to make a comment on the Equivalence Principle (EP) at this point. In our view, as in the Machian view as expressed by Sciama [12], the EP is a property of the gravitational interaction with the Universe. The inertial mass is just the gravitational mass scaled by the local gravitational potential (in units of c^2) due to the massive Universe. Therefore, the ratio of the gravitational mass and the inertial mass is a property of the Universe and not of the test particle! Thus there is no surprise in the perfect validity of the classical Equivalence Principle. A violation of the EP can arise only when there are new long range forces that have properties different from the gravitational coupling.

6.2 Lorentz invariance of fundamental equations

We have seen that the Maxwell's equations are invariant under the frame transformations in Cosmic Relativity, since we deduced that the velocity of light is a constant in all frames if it is a fundamental constant in the cosmic frame. We need to ensure that the same Lorentz invariance applies to a general interval between two space-time events, and also for relativistic wave equations.

The interval between two space-time events in the cosmic rest frame is

$$ds^2 = c^2 dt^2 - (dx^2 + dy^2 + dz^2) \quad (43)$$

and in another frame moving with respect to the cosmic frame with velocity V is

$$ds'^2 = c^2 dt'^2 - (dx'^2 + dy'^2 + dz'^2) \quad (44)$$

We have already shown that when $ds = 0$, for light, the two expressions are identical since velocity of light cannot depend on the state of motion of the frame, and Lorentz transformations follow from this. Now we apply the Lorentz transformations to the finite nonzero intervals to see whether these intervals are invariant. These are

$$\begin{aligned} x' &= \gamma(x - Vt) \\ t' &= \gamma(t - Vx/c^2) \end{aligned} \quad (45)$$

$$\gamma = (1 - V^2/c^2)^{-1/2}.$$

Since $dy' = dy$ and $dz' = dz$, we need to consider only $ds'^2 = c^2 dt'^2 - dx'^2$. Substituting the Lorentz transformations we see that $ds'^2 = ds^2$. Thus what is good for light is also good for all space-time intervals.

If $E = mc^2$ is the energy, $p = mv$ the momentum and m the mass of a particle in the cosmic rest frame, the Lorentz transformed quantities are $E' = \gamma mc^2$, and $p' = \gamma mv$. Then

$$E'^2 - p'^2 = E^2 - p^2 = m^2 c^4 \quad (46)$$

Therefore the Lorentz invariance of the Klein-Gordon equation and the Dirac equation will be valid in Cosmic Relativity. If these equations are valid in the cosmic rest frame, they are valid in all frames moving relative to the cosmic frame. The validity of the form of a physical law in all frames is not an assumption, unlike in SR. If the physical law is valid in the cosmic rest frame, *it is shown to be valid* in all frames in arbitrary motion relative to the cosmic rest frame.

6.3 Conceptual and philosophical implications

There has been a significant change, in fact the most profound and far reaching, in the philosophical view on space and time after Einstein's relativity theory became understood. The development of Cosmic Relativity and experimental evidence favouring it will imply a large shift in our world-view. The new world-view will of course be different from the one existed in pre-SR days, though Cosmic Relativity brings into focus a preferred frame we call the cosmic rest frame or the absolute frame. Since there is no ether, and since the new circumstances arise in acknowledging the gravitational presence of the Universe, a world-view based on Cosmic Relativity will be different from the one induced by Lorentzian Relativity or Special Relativity. It is important to note that the only aspect of the cosmos we have used in deducing a new theory relativity is its approximate homogeneity and isotropy, and the fact that the Universe is nearly at critical density. There is no use of any General Relativity. On the other hand, it is possible to start from Einstein's equations and the standard Robertson-Walker metric as a solution to it, and then deduce the results of Cosmic Relativity. There is complete consistency between the two. It may be noted the all the physical effects we talked about can be derived rigorously in this manner, though it is sufficient to use a post-Newtonian approximation to relativistic gravity to deduce these effects. This

implies that denying Cosmic Relativity is equivalent to denying the applicability of results from General Relativity (or any metric or scalar-tensor relativistic theory of gravitation) to clocks and scales moving in a massive Universe.

General Relativity follows from Cosmic Relativity more naturally than from Special Relativity because all general relativistic solutions have to take into account of the asymptotic or global properties of space and time. Also, SR is strictly applicable only to inertial observers, whereas Cosmic Relativity is applicable for general motion. In fact, Einstein himself had commented on the fact that General Relativity somehow brings back the possibility of an abstract ether [21], without the mechanical properties that were assigned to it in the pre-SR days.

There is also the question whether there should be a change in our attitude towards quantizing gravity. Space and time are unobservables, and really has no meaning in the absence of matter. It is matter that defines, facilitates, and modifies measurements of spatial and temporal intervals. Therefore, attempting to quantize space and time (and perhaps worse, space-time as a single entity) as if they have a fundamental physical existence is perhaps meaningless in the Machian sense.

I will comment on these aspects in detail in a separate paper. At present it suffices to mention that everything we know in General Relativity is consistent with Cosmic Relativity, and the harmony between the two is even better than in the case of General Relativity and Special Relativity.

Our approach to the theory of relativity answers many fundamental questions asked in the context of relativity of motion. Already one can see in Sciamma's demonstration [12] of inertial reaction arising from the gravitational interaction of the Universe a synthesis of Newton's first and second laws, and their relation to his law of gravity [22]. These connections are completed by Cosmic Relativity. We can now answer some of the doubts raised by Julian Barbour in his book, "Absolute or Relative Motion?: Discovery of Dynamics" on such connections [23]. Cosmic Relativity strengthens these connections further, and fully extends Machian ideas to all of physics by demonstrating that relativistic modifications of spatial and temporal intervals, as well as several important effects specific to quantum systems, are the results of the gravitational interaction of the Universe with the local physical system. The greatest surprise is the revelation that observed relativistic effects on clocks and scales in flat space-time themselves are fully Machian.

The construction of Cosmic Relativity also answers the important ques-

tion whether there is a second Mach's principle for time [24]. All modifications of temporal intervals, and even the relativity of simultaneity arising from the limitation of the maximum velocity possible for any entity in this Universe are indeed gravitational effects of the Universe. I did not stress on these aspects in this paper since most of the physicists think that ideas of Machian flavour are philosophical in nature, without relevance to physics and its calculations. This is a severe misunderstanding I will attempt to clarify in a separate paper, addressed to both physicists and philosophers.

Acknowledgements: I have benefitted from encouragement, suggestions and criticisms by several colleagues and friends in building up these ideas from considerations of our inseparable links with the Universe. Comments on the preliminary versions of the paper as well as on the talks presenting these ideas since December 2003 have helped considerably in sharpening the ideas, and the presentation. I would like to particularly thank C. V. K. Baba, A. P. Balachandran, G. T. Gillies, N. Kumar, M. B. Kurup, Martine Armand, D. Narasimha, R. Nityananda, Anna Nobili, G. Rajasekharan, V. Radhakrishnan, Joseph Samuel, Venzo de Sabbata, Sundar Sarukkai, Sukant Saran, Vikram Soni, B. V. Sreekantan, E. C. G. Sudarshan, D. Suresh, A. R. Usha Devi, and Matt Walhout.
